This paper presents a coupling technique for integrating the fractal finite element method (FFEM) with element-free Galerkin method (EFGM) for analyzing homogeneous, isotropic, and two-dimensional linear-elastic cracked structures subjected to Mode I loading condition. FFEM is adopted for discretization of domain close to the crack tip and EFGM is adopted in the rest of the domain. In the transition region interface elements are employed. The shape functions within interface elements which comprise both the element-free Galerkin and the finite element shape functions, satisfy the consistency condition thus ensuring convergence of the proposed coupled FFEM-EFGM. The proposed method combines the best features of FFEM and EFGM, in the sense that no structured mesh or special enriched basis functions are necessary and no post-processing (employing any path-independent integrals) is needed to determine fracture parameters such as stress-intensity factors (SIFs) and $T$-stress. The numerical results show that SIFs and $T$-stress obtained using the proposed method, are in excellent agreement with the reference solutions for the structural and crack geometries considered in the present study. Also a parametric study is carried out to examine the effects of the integration order, the similarity ratio, the number of transformation terms, and the crack-length to width ratio, on the quality of the numerical solutions.

Keywords: crack, Element-free Galerkin method, Fractal Finite Element Method, Stress-Intensity Factor, $T$-stress, Linear-Elastic Fracture Mechanics, Mode I.

1. INTRODUCTION

Recently, the methods based on fractal geometry concepts to generate infinite number of finite elements around the crack tip to capture the crack tip singularity, have been developed or investigated to solve linear-elastic fracture mechanics (LEFM) problems [1–5]. The fractal finite element method (FFEM) is one of such methods developed for calculating SIFs in linear-elastic crack problems. Since its origin, it has been successfully applied to solve many kinds of crack problems under Mode I and mixed mode loading conditions in 2D [6–15] and 3D [16]. Basically, FFEM separates a 2D or 3D cracked elastic body into a regular and a singular regions (see Fig. 1), with the latter enclosing the crack tip. Both the regular and the singular regions are modelled by conventional isoparametric finite elements. However, within the singular region an infinite number of elements are generated by a self-similar, fractal process to capture the singular behaviour at the crack tip. The nodal displacements in the singular region are transformed to a set of unknown coefficients using Williams analytical solution for the displacements near the crack tip [17]. Since the stiffness matrix of an isoparametric element depends only on its shape and not its actual dimensions, the above transformation can be performed at the element level and the results summed up as a geometrical progression series to be assembled to the global stiffness matrix. The contributions of the infinite number of elements in the singular region are therefore fully accounted for, while the number of degrees of freedom involved remains finite.

Compared with other numerical methods like the finite element method (FEM), FFEM has several advantages. First, by using the concept of fractal geometry, infinite number of finite ele-
ments can be generated virtually around the crack tip, and hence the effort for data preparation is minimized. Second, based on the eigenfunction expansion of the displacement fields [17, 18], the infinite number of finite elements that generate virtually by fractal geometry around the crack tip are transformed in an expeditious manner. This results in reducing the computational time and the memory requirement for fracture analysis of cracked structures. Third, no special finite elements and post-processing are needed to determine the SIFs and $T$-stress. Finally, as the analytical solution is embodied in the transformation, the accuracy of the predicted SIFs and $T$-stress is high.

In recent years, as an alternative to FEM, a class of meshfree or meshless methods, such as the element-free Galerkin method (EFGM) [19–21], has emerged to demonstrate significant potential for solving moving boundary problems typified by growing cracks. Fundamental to all meshless methods, a structured mesh is not used, since only a scattered set of nodal points is required in the domain of interest. This feature presents significant implications for modeling fracture propagation, because the domain of interest is completely discretized by a set of nodes. Since no element connectivity data are needed, the burdensome remeshing required by FEM is avoided. A growing crack can be modeled by simply extending the free surfaces, which correspond to the crack. By sidestepping remeshing requirements, crack-propagation analysis can be dramatically simplified.

Although meshless methods are attractive for simulating crack propagation, because of their versatility, the computational cost of a meshless method typically exceeds the cost of a regular FEM. Furthermore, given the level of maturity and comprehensive capabilities of FEM, it is often advantageous to use meshless methods only in the sub-domains, where their capabilities can be exploited to the greatest benefit. In modeling the crack propagation in a complex engineering structure with stiffeners, connections, welds, etc., it is more effective to apply meshless methods at the sites of potential crack growth and FEM in the remainder of the domain. Therefore, numerical methods need to be developed for combining meshless and finite element methods.

This paper presents a coupling technique for integrating FFEM with EFGM for analyzing homogeneous, isotropic, and two-dimensional linear-elastic cracked structures subjected to Mode I loading condition. FFEM is adopted for discretization of domain close to the crack tip and EFGM is adopted in the rest of the domain. In the transition region, interface elements are employed. The interface element shape functions which comprise both the element-free Galerkin and the finite element shape functions, satisfy the consistency condition thus ensuring convergence of the proposed coupled FFEM-EFGM. The proposed method combines the best features of FFEM and EFGM, in the sense that no structured mesh or special enriched basis functions are necessary and no post-processing (employing any path-independent integrals) is needed to determine fracture
parameters such as SIFs and T-stress. Three numerical examples are presented to illustrate the proposed coupled FFEM-EFGM by calculating SIFs and T-stress.

2. Fractal Finite Element Method

As depicted in Fig. 1, FFEM divides the domain of a two-dimensional body into a regular and a singular region, with the latter enclosing the crack tip. In Fig. 1, the boundary curve $\Gamma_0$ separates the two regions. Both the regular and singular regions are modeled using conventional finite elements. With the crack tip as the centre of similarity and using $\xi$ as the similarity ratio, an infinite set of curves $\{\Gamma_1, \Gamma_2, \ldots\}$, similar to $\Gamma_0$ but with proportional constants $(\xi^1, \xi^2, \ldots)$, are generated inside the singular region. Between the two curves $\Gamma_{k-1}$ and $\Gamma_k$, the region is named the $k$-th layer.

Straight lines that connect the crack tip to the corner nodes lying on $\Gamma_0$ are then created, dividing each layer into a mesh of elements with a similar pattern in the process. A fractal mesh is thus generated in the singular region with conventional finite elements only being used. All nodes located on $\Gamma_0$ are called the master nodes (m), while those inside $\Gamma_0$ are called the slave nodes (s).

2.1. Williams eigenfunction expansion

For a plane crack with traction-free faces subjected to arbitrary far field loading, the linear elastic displacement field at the crack tip obtained by the Williams eigenfunction expansion technique [17] can be expressed as

$$u_1 = \sum_{n=0}^{\infty} \frac{r^{n/2}}{2\mu} \left[ a_n \left( \left( \frac{\kappa}{2} + \frac{n}{2} \right) \cos \frac{n}{2} \theta - \frac{n}{2} \cos \left( \frac{n}{2} - 2 \right) \theta \right) \right],$$

$$u_2 = \sum_{n=0}^{\infty} \frac{r^{n/2}}{2\mu} \left[ a_n \left( \left( \frac{\kappa}{2} - \frac{n}{2} \right) \sin \frac{n}{2} \theta + \frac{n}{2} \sin \left( \frac{n}{2} - 2 \right) \theta \right) \right],$$

where $\mu$ is the shear modulus, $(r, \theta)$ are the polar coordinates, $\kappa = (3 - \nu)/(1 + \nu)$ for plane stress and $\kappa = 3 - 4\nu$ for plane strain, with $\nu$ being the Poisson’s ratio.

The coefficients $a_n$ can be determined after imposing loading and other boundary conditions. Mode-I SIF, $K_I$, is related to the first degree coefficients ($a_1$) in the series which is directly associated with the $r^{-1/2}$ term accounting for the singular stress behaviour at the crack tip, as follows:

$$a_1 = \frac{K_I}{\sqrt{2\pi}}.$$

The first non-singular stress term, which acts parallel to the crack tip, of the Williams eigenfunction expansion series and is known as $T$-stress, can be related to the coefficient ($a_2$), as follows

$$T = 4a_2.$$

2.2. Fractal transformation

In conventional FEM, according to the conservation of strain energy the stiffness equation system can be written as

$$Kd = f,$$
where $K$ is the stiffness matrix, $d$ is the nodal displacement vector and $f$ is the nodal force vector. For the regular region, the stiffness equation system can be partitioned with respect to the nodes other than the master nodes ($r$) and the master nodes ($m$) as follows:

$$
\begin{bmatrix}
K_{rr}^{R} & K_{rm}^{R} \\
K_{mr}^{R} & K_{mm}^{R}
\end{bmatrix}
\begin{bmatrix}
d_r \\
d_m
\end{bmatrix}
= 
\begin{bmatrix}
f_r^{R} \\
f_m^{R}
\end{bmatrix},
$$

(6)

where $d_r$ are the displacements of the nodes in the regular region other than the master nodes ($r$), and $d_m$ are the displacements of the master nodes ($m$), etc. Similarly, for the first layer in the singular region, the stiffness equation system

$$K^{1st}d^{1st} = f^{1st},$$

(7)

can be partitioned with respect to the master nodes ($m$) and the slave nodes ($s$) as follows:

$$
\begin{bmatrix}
K_{mm}^{1st} & K_{ms}^{1st} \\
K_{sm}^{1st} & K_{ss}^{1st}
\end{bmatrix}
\begin{bmatrix}
d_m \\
d_s^{1st}
\end{bmatrix}
= 
\begin{bmatrix}
f_m^{1st} \\
f_s^{1st}
\end{bmatrix},
$$

(8)

where $d_s^{1st}$ are the displacements of the slave nodes ($s$) in the first layer of the singular region. Using the Williams eigenfunction expansion in Eqs. (1) and (2), $d_s^{1st}$ can be expressed as a function of the generalized coordinates $a = \{a_0, a_1, a_2, \ldots\}^T$ as

$$d_s^{1st}(r, \theta) = T_s^{1st}(r, \theta) a,$$

(9)

where $T_s^{1st} = T_s^{1st}(r, \theta)$ is a transformation matrix in terms of the polar coordinates $(r, \theta)$ for the slave nodes ($s$) in the first layer. Using the transformation matrix $T_s^{1st}(r, \theta)$ Eq. (8) can be transformed into

$$
\begin{bmatrix}
K_{mm}^{1st} & K_{ms}^{1st} \\
(T_s^{1st})^T K_{sm}^{1st} & (T_s^{1st})^T K_{ss}^{1st}
\end{bmatrix}
\begin{bmatrix}
d_m \\
(T_s^{1st})^T a
\end{bmatrix}
= 
\begin{bmatrix}
f_m^{1st} \\
(T_s^{1st})^T f_s^{1st}
\end{bmatrix},
$$

(10)

Since the second and subsequent layers in the singular region i.e. $k \geq 2$, comprise only the slave nodes ($s$), the final assembled global stiffness equation system has the form

$$
\begin{bmatrix}
K_{rr}^{R} & K_{rm}^{R} & 0 \\
K_{mr}^{R} & K_{mm}^{R} + K_{mm}^{1st} & K_{ms}^{1st} \\
0 & K_{sm}^{1st} & K_{ss}^{1st} + K_{ss}^{1nn}
\end{bmatrix}
\begin{bmatrix}
d \\
d_m \\
\end{bmatrix}
= 
\begin{bmatrix}
f_r^{R} \\
f_m^{1st} \\
(T_s^{1nn})^T f_s^{1nn}
\end{bmatrix},
$$

(11)

where $K_{ms}^{1nn} = K_{ms}^{1st} T_s^{1st}$, $K_{ss}^{1nn} = (T_s^{1nn})^T K_{ss}^{1nn} T_s^{1nn}$, $f_s^{1nn} = \sum_{k=2}^{\infty} (T_s^{knn})^T f_s^{knn}$, $f_s^{1nn} = (T_s^{1nn})^T f_s^{1nn}$, and $T_s^{1nn} = \sum_{k=2}^{\infty} (T_s^{knn})^T T_s^{knn}$ is a geometrical progression series and so we have

$$K_s^{1nn} = \left[ \xi - \frac{n_i + n_j}{2} \right]^{-1} (T_s^{1nn})^T K_s^{1st} (T_s^{1nn}),$$

(12)

where $n_i = (i - 1)$ for $i = 1, 2, 3, \ldots$. Based on a similar procedure, the global generalized force vector $T_s^{1nn}$ can also be expressed in terms of $f_s^{1nn}$. 

3. COUPLING PROCEDURE

The coupling between FFEM and EFGM domains is accomplished by introducing interface elements between those domains (see Fig. 2). In these interface elements, a hybrid displacement approximation is defined that satisfies displacement continuity across the interface boundaries. For the detailed characteristics of interface elements, the papers [22, 23] can be referred. FE and EFG displacement approximations are briefly outlined before interface elements are described in detail. For displacement approximation in the Galerkin procedure, both FE and EFG use similar forms:

\[ u^h_i(x) = \sum_{I=1}^{n} \tilde{\Phi}_I(x) d_{iI}, \]  

(13)

where \( u^h_i(x) \) is the nodal value of displacement component \( i \) at point \( x \), \( \tilde{\Phi}_I(x) \) are shape functions that depend on the method, and \( d_{iI} \) are the nodal parameters of displacement component \( i \) at node \( I \).
3.1. FE shape functions

The displacement approximation $u_i$, in an isoparametric element is given by

$$u_i^h(x) = \sum_{I=1}^{n_{en}} N_I(\xi(x)) d_{iI}, \quad x \in \Omega_e^F,$$

(14)

where $n_{en}$ is the number of element nodes. Because Q8 (8-node serendipity) and L9 (9-node Lagrangian) elements are used in FFEM discretization, in the present study a 5-node element is adopted for interface elements, the shape functions, $N_I (I = 1 − 5)$ of which in the parent domain $(\xi \in [-1, 1], \eta \in [-1, 1])$ (see Fig. 2) are as follows:

$$N_1 = \frac{1}{4} (\xi - 1)(1 - \eta), \quad N_2 = \frac{1}{4} (\xi + 1)(1 - \eta),$$

$$N_3 = \frac{1}{4} (\xi + 1)(1 + \eta), \quad N_4 = \frac{1}{4} (1 - \xi)(1 + \eta),$$

$$N_5 = \frac{1}{2} (1 - \xi^2)(1 - \eta).$$

(15)

3.2. EFG shape functions

In the EFG method, the displacement is approximated by moving least-squares approximations (MLS) [24]. The MLS approximation $u_i^h(x)$ is given by

$$u_i^h(x) = \sum_{I=1}^{n} \Phi_I(x) d_{iI}, \quad x \in \Omega_E,$$

(16)

where $n$ is the number of nodes in the neighborhood of $x$, for which the weight function $w_I(x) > 0$ and the EFG shape functions are defined as

$$\Phi_I(x) = \sum_{J=1}^{m} p_J(x) [A^{-1}(x)C(x)]_{JI},$$

(17)

with $p(x)$ being a vector of complete basis functions of order $m$, and $A(x) = \sum_{I=1}^{n} w_I(x)p(x_I)p^T(x_I)$ and $C(x) = [w_1(x)p(x_1), w_2(x)p(x_2), \ldots, w_n(x)p(x_n)]$.

In the present study, a linear basis in two dimensions, $p^T(x) = \{1, x_1, x_2\}$, $m = 3$ in conjunction with the following exponential weight function [19] is used,

$$w_I(x) = w_I(r) = \begin{cases} 
\frac{e^{-(r/c)^2} - e^{-(1/c)^2}}{1 - e^{-(1/c)^2}} & 0 \leq r \leq 1 \\
0 & r > 1
\end{cases},$$

(18)

where $c$ is a parameter that sets the relative weight inside the domain of influence (in the present study $c = 0.25$ is adopted), $r = z_I/z_{mI}$ with $z_I = ||x - x_I||$ being the distance from a sampling point $x$ to a node $x_I$, $z_{mI}$ being the domain of influence of node $I$ such that

$$z_{mI} = z_{\max} z_{cI};$$

(19)

here $z_{cI}$ is the characteristic nodal spacing distance which is chosen such that the node $I$ has the number of neighbors sufficient for regularity of $A(x)$ (which is used to determine the MLS approximation), and $z_{\max}$ is a scaling parameter.
3.3. Interface displacement approximation

A detailed schematic of interface domain is shown in Fig. 2. In $\Omega_E$, the displacement at a point is approximated using the MLS approximants in Eq. (16), and in $\Omega_F$, the FE interpolants in Eq. (14) are employed in each element subdomain $\Omega_E^i$. In $\Omega_I$, the interface region, the displacement at a point is approximated using the following expression:

$$ u_h^i(x) = u_{i}^{FE}(x) + R(x) \left[ u_{i}^{EFG}(x) - u_{i}^{FE}(x) \right] $$

$$ \equiv [1 - R(x)] u_{i}^{FE}(x) + R(x) u_{i}^{EFG}(x), \quad x \in \Omega_I, $$

where $u_{i}^{FE}$ and $u_{i}^{EFG}$ are approximations for $u_i$ in $\Omega_I$ given by the FE and EFG approximations, respectively, and $R(x)$ is a ramp function [25] for coupling the FE and EFG regions. $R(x)$ is defined using the FE shape functions in Eq. 14:

$$ R(x) = \sum_{x_I \in \Gamma_E} N_J(x). $$

It can be verified that

$$ R(x) = \begin{cases} 1 & x \in \Gamma_E \\ 0 & x \in \Gamma_F \end{cases}, $$

and it varies linearly along interface element boundaries adjacent to other interface elements. Therefore, the approximation Eq. (20) reduces to $u_{i}^{EFG}$ Eq. (16) on $\Gamma_E$ and $u_{i}^{FE}$ Eq. (14) on $\Gamma_F$, ensuring continuity. The interface shape functions can be developed by substituting the displacement approximations Eqs. (14) and (16) into Eq. (20):

$$ u_h^i(x) = [1 - R(x)] \sum_{I=1}^{n_{en}} N_I(\xi(x))d_{II} + R(x) \sum_{I=1}^{n_{sn}} \Phi_I(x)d_{II} \equiv \sum_{I=1}^{n_{sn}} \overline{\Phi}_I(x)d_{II}, \quad x \in \Omega^r_F, $$

where the interface shape functions $\overline{\Phi}_I(x)$ are

$$ \overline{\Phi}_I(x) = \begin{cases} [1 - R(x)] N_I(\xi(x)) + R(x) \Phi_I(x) & x_I \in \Omega^r_I, \\ R(x) \Phi_I(x) & x_I \notin \Omega^r_I. \end{cases} $$

4. Variational formulation and discretization

For small displacements in two-dimensional, homogeneous, isotropic and linear-elastic solids, the equilibrium equations and boundary conditions are

$$ \nabla \cdot \sigma + b = 0 \quad \text{in} \quad \Omega $$

and

$$ \sigma \cdot n = \vec{t} \quad \text{on} \quad \Gamma_t \quad \text{(natural boundary conditions)}, $$

$$ \mathbf{u} = \mathbf{\overline{t}} \quad \text{on} \quad \Gamma_u \quad \text{(essential boundary conditions)}, $$

respectively, where $\sigma = D\varepsilon$ is the stress vector, $D$ is the material property matrix, $\varepsilon = \nabla \cdot \mathbf{u}$ is the strain vector, $\mathbf{u}$ is the displacement vector, $b$ is the body force vector, $\vec{t}$ and $\mathbf{\overline{t}}$ are the vectors of prescribed surface tractions and displacements, respectively, $\mathbf{n}$ is a unit normal to the domain $\Omega$, $\Gamma_t$ and $\Gamma_u$ are the portions of boundary, $\Gamma$ where tractions and displacements are prescribed,
respectively, $\nabla^T = \{\partial/\partial x_1, \partial/\partial x_2\}$ is the vector of gradient operators, and $\nabla u$ is the symmetric part of $\nabla u$.

Since the nodal parameters and the nodal displacements are the same in the finite elements, essential boundary conditions in the FFEM region can be applied by adopting the procedures similar to that in the FE analysis. In the following, the concept of application of essential boundary conditions in the EFGM and the transition regions is outlined. For an easy illustration, consider a single boundary constraint, $\Pi_i(x_j) = g_i(x_j)$ applied at node $J$ (which belongs to the EFGM region or the transition region) in the direction of coordinate $x_i$. Then, the variational or weak form of Eqs. (25) and (26) can be expressed by

$$
\int_\Omega \sigma^T \epsilon d\Omega + f_i(x_j) \delta u_i(x_j) = \int_\Omega b^T \delta u d\Omega - \int_{\Gamma_t} t^T \delta u d\Gamma,
$$

(27)

$$
\delta f_i(x_j) [u_i(x_j) - g_i(x_j)] = 0,
$$

(28)

where $f_i(x_j)$ and $u_i(x_j)$ are the $i$th component of $f(x_j)$ and $u(x_j)$, respectively. From Eqs. (13), (14), (16) and (23), the approximation of $u_i(x_j)$ can be written as

$$
u_i^h(x_j) = \sum_{l=1}^{N} \Phi_l(x_j) d_{il},
$$

(29)

where

$$
\Phi_l(x) = \begin{cases} 
N_l (\xi(x)) & x \in \Omega_E^r \\
\Phi_l(x) & x \in \Omega_E \\
\Phi_l(x) & x \in \Omega_E^s
\end{cases}
$$

(30)

and $N$ is the total number of nodal points in $\Omega$. Using Eqs. (29) and (30) in the coupled FFEM-EFGM discretization (involving the master nodes $(m)$, the slave nodes $(s)$ and the nodes other than the master nodes $(r)$) of Eqs. (27) and (28) and application of the FFEM concepts outlined in Sec. 2, results in

$$
\begin{bmatrix}
K_{rr}^R & K_{rm}^R & 0 \\
K_{mr}^R & K_{mm}^R + K_{1st} & K_{ms}^{1st} \\
0 & K_{sm}^{1st} & K_{ss} + K_{inn}
\end{bmatrix}
\begin{bmatrix}
\tilde{\Phi}_J^T \\
d_r \\
d_m
\end{bmatrix}
= 
\begin{bmatrix}
f_{m}^R + f_{m}^{\text{sl}} \\
f_{s}^{\text{sl}} + f_{s}^{\text{inn}}
\end{bmatrix},
$$

(31)

where the submatrices and the subvectors in Eq. (31) are respectively obtained by partitioning and transforming the global stiffness matrix, whose the $IJ$-th component is given by

$$
[K]_{IJ} = \int_\Omega B^T_J D B_J d\Omega \in \mathbb{R}^2 \times \mathbb{R}^2,
$$

(32)

and the global force vector whose $I$-th component is given by

$$
[f]_I = \int_\Omega \tilde{\Phi}_J b^T d\Omega - \int_{\Gamma_t} \tilde{\Phi}_J t^T d\Gamma \in \mathbb{R}^2.
$$

(33)

In Eq. (32), $B_J$ and $D$ are respectively the strain displacement matrix and the linear elastic constitutive matrix.
In order to perform numerical integration in Eqs. (32) and (33), a background mesh is needed in the EFGM and in the transition regions. This background mesh can be independent of the arrangement of nodes; however, the nodes of the background mesh may coincide with the nodes in the EFGM and in the transition regions. In the present study, standard Gaussian quadrature is used to evaluate the integrals for assembling the stiffness matrix and the force vector by adopting $8 \times 8$ quadrature in the EFGM and in the transition regions. In the FFEM region, the integration order is varied from $2 \times 2$ to $4 \times 4$ quadrature to study its effect on the quality of the numerical solutions.

5. Essential Boundary Conditions

Lack of Kronecker’s delta properties in the meshless shape functions, $\Phi_I$, poses some difficulties in imposing essential boundary conditions in the EFGM and in the transition regions. Nevertheless, several methods are currently available for enforcing essential boundary conditions. In this work, a full transformation method [26, 33] is adopted.

Consider the following transformation relating the nodal parameters and the nodal displacements of the master nodes ($m$), and the nodes other than the master nodes ($r$),

$$\begin{pmatrix} \hat{d}_r \\ \hat{d}_m \end{pmatrix} = \Lambda \begin{pmatrix} d_r \\ d_m \end{pmatrix}, \quad (34)$$

where $\hat{d}_m$ and $\hat{d}_r$ are respectively the nodal displacements of the master nodes ($m$), and the nodes other than the master nodes ($r$), and

$$\Lambda = \begin{bmatrix} \Phi_1^{-T} \\ \Phi_1^{-2T} \\ \Phi_2^{-T} \\ \Phi_2^{-2T} \\ \vdots \end{bmatrix}^{(r)} \begin{pmatrix} 0 \\ \Phi_1^{(r)} \\ \Phi_1^{(r)} \Phi_2^{-T} \\ \Phi_2^{(r)} \end{pmatrix}^{(r+1)}$$

is the transformation matrix. Note that along $\Gamma_F$ which contains the master nodes ($m$), the interface shape functions $\overline{\Phi}_I(x)$ reduces to the finite element shape functions in Eq. (15). Multiplying the first two sets of matrix equations in Eq. (31) by $\Lambda^{-T}$, one obtains
that the discretization (shown in Figs. 4a and 4b) and the number of fractal transformation terms assumed. The number of fractal transformation terms used in (i) the effect of the scaling parameter convergence is checked against Q8 and L9 fractal mesh configurations. The convergence study includes: (ii) the effect of the fractal analysis of the problems presented in Examples 2–3. In all the numerical examples, elastic modulus region on the solution. The experience gained in the convergence study of Example 1 is used to (iii) the effect of the fractal on the estimates of FFEM-EFGM. In Example 1, in order to check the numerical accuracy and stability, convergence studies on the estimates of leads to the following equation: 6.6. Numerical Examples

Three numerical examples comprising of single edge crack tension (SECT), double edge crack tension (DECT) and center crack tension (CCT) are presented to illustrate the proposed coupled FFEM-EFGM. In Example 1, in order to check the numerical accuracy and stability, convergence studies on the estimates of $K_f$ and $T$-stress using the proposed method are performed. The convergence is checked against Q8 and L9 fractal mesh configurations. The convergence study includes: (i) the effect of the scaling parameter $z_{\text{max}}$ in the EFGM region on the solution; (ii) the effect of the integration order adopted in the FFEM region on the accuracy; (iii) the effect of the fractal mesh size on the accuracy; and (iv) the effect of different weight functions adopted in the EFGM region on the solution. The experience gained in the convergence study of Example 1 is used to analyze the problems presented in Examples 2–3. In all the numerical examples, elastic modulus $E$ and Poisson’s ratio $\nu$ are assumed to be $30 \times 10^6$ units and 0.25 respectively.

6.1. Example 1: Single Edge Crack Tension (SECT) Specimen

Consider a single edge crack tension specimen as shown in Fig. 3, that has length $2L = 3$ units, width $W = 1$ unit, and crack length $a = 0.5$ units. The far-field tensile stress, $\sigma = 1$ unit. Due to symmetry, only half of the plate is analyzed. Effect of both Q8 and L9 fractal mesh configurations on the estimates of $K_f$ and $T$-stress are examined. Typical coupled FFEM-EFGM discretization with L9 fractal mesh configurations of rectangular and circular shapes having a similarity ratio $\xi$ of 0.8, are shown in Figs. 4a and 4b respectively. The size of fractal mesh (distance from the crack tip to the curve $I_0$ on which the master nodes ($m$) are located) is $0.5a$. Plane stress condition is assumed. The number of fractal transformation terms used in $T_s^{k-\text{th}}$ is 20. It can be easily verified that the discretization (shown in Figs. 4a and 4b) and the number of fractal transformation terms

\[
\left[ \begin{array}{c} \mathbf{K}_{rr} \quad \mathbf{K}_{rm} \\ \mathbf{K}_{mr} \quad \mathbf{K}_{mm} + \mathbf{K}_{mm}^{1st} \\ 0 \quad \mathbf{K}_{sm}^{1st} \\ \mathbf{\Phi}_J^T \end{array} \right] \left[ \begin{array}{c} \mathbf{0} \\ \mathbf{K}_{ms}^{1st} + \mathbf{K}_{ss}^{1st} \\ 0 \\ \mathbf{0} \end{array} \right] \left[ \begin{array}{c} \mathbf{\Phi}_J^T \\ \mathbf{0} \end{array} \right] = \left[ \begin{array}{c} \mathbf{d}_r \\ \mathbf{d}_m \\ \mathbf{a} \end{array} \right] \left[ \begin{array}{c} f_i(x_j) \\ \mathbf{0} \end{array} \right].
\]

Exchanging the rows to replace the redundant equations by the constraint equation using the procedure outlined in [26, 33], leads to the following equation:

\[
\mathcal{K} \begin{bmatrix} \mathbf{d}_r \\ \mathbf{d}_m \\ \mathbf{a} \end{bmatrix} = \mathcal{F},
\]

where $\mathcal{K}$ and $\mathcal{F}$ are the modified stiffness matrix and force vectors respectively. Using Eq. (37), $\{d_r \ d_m \ a\}^T$ can be solved efficiently without needing any Lagrange multipliers. In the case of multiple boundary constraints, similar procedures are repeated. Knowing $a = \{a_0, a_1, a_2, \ldots\}^T$, SIFs and $T$-stress can be calculated using Eqs. (3) and (4) respectively.

6.1. Example 1: Single Edge Crack Tension (SECT) Specimen

Consider a single edge crack tension specimen as shown in Fig. 3, that has length $2L = 3$ units, width $W = 1$ unit, and crack length $a = 0.5$ units. The far-field tensile stress, $\sigma = 1$ unit. Due to symmetry, only half of the plate is analyzed. Effect of both Q8 and L9 fractal mesh configurations on the estimates of $K_f$ and $T$-stress are examined. Typical coupled FFEM-EFGM discretization with L9 fractal mesh configurations of rectangular and circular shapes having a similarity ratio $\xi$ of 0.8, are shown in Figs. 4a and 4b respectively. The size of fractal mesh (distance from the crack tip to the curve $I_0$ on which the master nodes ($m$) are located) is $0.5a$. Plane stress condition is assumed. The number of fractal transformation terms used in $T_s^{k-\text{th}}$ is 20. It can be easily verified that the discretization (shown in Figs. 4a and 4b) and the number of fractal transformation terms...
Fig. 3. Single edge crack tension specimen with geometry and loads.

adopted in the analysis, result in the total number of unknowns to be solved in Eq. (37) as 138. In the EFGM and the transition regions $8 \times 8$, Gaussian quadrature is adopted, whereas in the FFEM region the integration order is varied from $2 \times 2$ to $4 \times 4$ quadrature to study its effect on the quality of the numerical solutions. The analytical solution of $K_I$ for SECT specimen given by Tada et al. [34], for different $a/W$ ratios is as follows:

$$K_I = \sigma \sqrt{\frac{a}{\pi}} \sqrt{\frac{2W}{\pi a}} \tan \frac{a}{2W} \left[ 0.752 + 2.02 \frac{(a/W)}{\pi a} + 0.37 \left( 1 - \sin \frac{\pi a}{2W} \right)^3 \right].$$

Similarly, the analytical solution of $T$-stress for SECT specimen with $L/W = 1.5$ is given by Fett [35], for different values $a/W$ ratios.
Table 1 shows the results of parametric study carried out by varying the scaling parameter $z_{\text{max}}$ in the EFGM region, using exponential weight function. In the FFEM region, the $2 \times 2$ Gaussian integration is used. It can be observed from Table 1 that for the discretization adopted (shown in Figs. 4a and 4b), $z_{\text{max}} = 2.51$ along with L9 elements, provides accurate estimates of $K_I/ (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ values, when compared with the benchmark solution of $K_I/ (\sigma \sqrt{\pi a}) = 2.8266$ units [34] and $T (1 - a/W)^2 / \sigma = -0.106$ units [35].

$^a$ SIF ratio $= (K_I/ (\sigma \sqrt{\pi a})$ by proposed method)/2.8266.

$^b$ $T$-stress ratio $= (T (1 - a/W)^2 / \sigma$ by proposed method)/−0.106.

The effect of the integration order adopted in the FFEM region on the quality of the estimates of $K_I/ (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ is studied, using the coupled FFEM–EFGM discretization with fractal mesh configurations of rectangular and circular shapes, as shown in Figs. 4a and 4b respectively. The similarity ratio, the number of fractal transformation terms, the size of fractal mesh, and $z_{\text{max}}$ are respectively 0.8, 20, 0.5a and 2.51. In the EFGM region, the exponential weight function is used. Table 2 presents the results of $K_I/ (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ obtained using different integration orders in the FFEM region for fractal mesh configurations of rectangular and circular shapes. It can be observed from Table 2 that convergent and accurate estimates of $K_I/ (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ can be obtained by adopting $2 \times 2$ Gaussian integration in the FFEM region.

Table 3 shows the effect of the nodal refinement in the EFGM region alone (keeping the discretization in FFEM region unchanged) on the predicted $K_I/ (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ values, obtained using exponential weight function along with Q8 and L9 elements for fractal mesh configurations of rectangular and circular shapes. The similarity ratio, the number of fractal transformation terms, the size of fractal mesh and $z_{\text{max}}$, are respectively 0.8, 20, 0.5a and 2.51. In the FFEM region $2 \times 2$ Gaussian integration is used. Table 3 also includes the details of the total number of unknowns to be solved in Eq. (37) for the discretization and the number of fractal transformation terms adopted. It can be observed from Table 3 that the nodal refinement in EFGM region alone has very small influence on the accuracy of $K_I/ (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ estimates obtained using L9 elements, when compared with those obtained using Q8 elements. The convergence of the solutions with respect to the nodal refinement in the EFGM region alone, obtained by means of L9 elements shows more stability than those obtained using Q8 elements.

\(^a\) SIF ratio = \( (K_I/(\sigma\sqrt{\pi a}) \) by proposed method)/2.8266.

\(^b\) \( T \)-stress ratio = \( (T(1-a/W)^2/\sigma \) by proposed method)/-0.106.
Using the proposed method, the effect of the fractal mesh size is studied, using the coupled FFEM-EFGM discretization with fractal mesh configurations of rectangular and circular shapes similar to that shown in Figs. 4a and 4b respectively. The similarity ratio, the number of fractal transformation terms and $z_{\text{max}}$, are respectively 0.8, 20, and 2.51. In the FFEM region, the $2 \times 2$ Gaussian integration is used. In the EFGM region exponential weight function is used. Table 4 shows the results of $K_I/(\sigma \sqrt{\pi a})$ and $T(1-a/W)^2/\sigma$, obtained using Q8 and L9 elements for fractal mesh configurations of rectangular and circular shapes. It can be observed from Table 4 that the results are insensitive to the fractal mesh sizes in combination with the similarity ratio, the number of fractal transformation terms, and the similarity ratio considered in the present study. In addition, from Table 4 it can be observed that the estimates of $K_I/(\sigma \sqrt{\pi a})$ and $T(1-a/W)^2/\sigma$ obtained using L9 elements are more accurate when compared with those obtained using Q8 elements.

$^a$ SIF ratio = $(K_I/(\sigma \sqrt{\pi a})$ by proposed method)/2.8266.

$^b$ T-stress ratio = $(T(1-a/W)^2/\sigma$ by proposed method)/-0.106.

Using the proposed method, the effect of the similarity ratio on the predicted $K_I/(\sigma \sqrt{\pi a})$ and $T(1-a/W)^2/\sigma$ values is studied by varying the similarity ratio $\xi$ from 0.1 to 0.9, using the coupled FFEM-EFGM discretization with fractal mesh configurations of rectangular and circular shapes similar to those shown in Figs. 4a and 4b respectively. The number of fractal transformation terms, the size of fractal mesh and $z_{\text{max}}$, are respectively 20, 0.5a and 2.51. In the FFEM region $2 \times 2$ Gaussian integration is used. In the EFGM region exponential weight function is used. Figures 5a and 5b show respectively the convergence of SIF ratio $(K_I/(\sigma \sqrt{\pi a})$ by the proposed method/2.8266) and T-stress ratio $(T(1-a/W)^2/\sigma$ by the proposed method/-0.106) estimates with the similarity ratio $\xi$ employed, for fractal mesh configurations of rectangular and circular shapes respectively. It can be observed from Figs. 5a and 5b that accuracy increases with the similarity ratio. This is quite natural, because finer fractal meshes will be generated for higher value of similarity ratios and therefore will give better results. However, when very high value of similarity ratio is used, numerical errors arise and cause large discrepancies. It can be observed from Figs. 5a and 5b that L9 elements produce better results when compared with those obtained using Q8 elements.
Mode I crack problems by coupled fractal finite element and meshfree method

Using the proposed method, the effect of the number of fractal transformation terms on the predicted $K_I / (\sigma \sqrt{\pi a})$ and $T (1 - a/W)^2 / \sigma$ values is studied, by varying the number of fractal transformation terms used in $T_{k-th}$ from 4 to 24. Coupled FFEM-EFGM discretization with fractal mesh configurations of rectangular and circular shapes, as shown in Figs. 4a and 4b respectively, is adopted. The similarity ratio, the size of fractal mesh and $z_{max}$ are respectively 0.8, 0.5a and 2.51. In the FFEM region $2 \times 2$ Gaussian integration is used. In the EFGM region exponential weight function is used. Figures 6a and 6b show respectively the convergence of SIF ratio and $T$-stress ratio estimates with the number of fractal transformation terms used, for fractal mesh configurations of rectangular and circular shapes, respectively. It can be observed from Figs. 6a and 6b that L9 elements produce better results when compared with those obtained using the Q8 elements.

For crack length-to-width ratio $a/W = 0.5$, the angular variations of the stress components $\sigma_{rr}$, $\sigma_{\theta\theta}$, and shear stress, $\tau_{r\theta}$ at radial distance to crack length $r/a = 0.01$, are shown in Fig. 7. Coupled
FFEM-EFGM discretization with L9 fractal mesh configurations of rectangular and circular shapes, as shown in Figs. 4a and 4b respectively, is used. The similarity ratio, the number of fractal transformation terms, the size of fractal mesh, and $z_{\text{max}}$, are respectively 0.8, 20, 0.5a and 2.51. In the FFEM region $2 \times 2$ Gaussian integration is used. In the EFGM region, exponential weight function is used. Figure 7 also includes the plots of exact stresses from the LEFM singularity field near the crack tip [36], obtained by using the benchmark solution of $K_I/\left(\sigma\sqrt{\pi a}\right) = 2.8266$ units [34]. The stresses predicted by the proposed method match very well with the exact stresses.

**Fig. 7.** Angular variations of $\sigma_{rr}$, $\sigma_{\theta\theta}$, and $\tau_{r\theta}$ (Example 1).

The effect of $a/W$ ratio on the estimates of $K_I/\left(\sigma\sqrt{\pi a}\right)$ and $T (1 - a/W)^2/\sigma$ is studied, using the coupled FFEM-EFGM discretization, with fractal mesh configurations of rectangular and circular shapes similar to that shown in Figs. 4a and 4b respectively. The similarity ratio, the number of fractal transformation terms and $z_{\text{max}}$, are respectively 0.8, 20, and 2.51. The size of fractal mesh for $a/W = 0.1 - 0.5$, 0.6, 0.7, 0.8, and 0.9 are respectively 0.5a, 0.333a, 0.214a, 0.125a, and 0.056a. In the FFEM region, $2 \times 2$ Gaussian integration is used. In the EFGM region, exponential weight function is used. Figures 8a and 8b show respectively the estimates of $K_I/\left(\sigma\sqrt{\pi a}\right)$ and $T (1 - a/W)^2/\sigma$ as a function of $a/W$ ratio, obtained using Q8 and L9 elements for fractal mesh configurations of rectangular and circular shapes. Figures 8a and 8b demonstrate that the estimates of $K_I/\left(\sigma\sqrt{\pi a}\right)$ and $T (1 - a/W)^2/\sigma$ as a function of $a/W$ ratio obtained using the proposed method are in good agreement with the benchmark solutions of $K_I/\left(\sigma\sqrt{\pi a}\right)$ [34] and $T (1 - a/W)^2/\sigma$ [35].

**Fig. 8.** Effect of $a/W$ ratio (Example 1); a) $K_I$, b) $T$-stress.
6.2. Example 2: Double Edge Crack Tension (DECT) Specimen

Consider a double edge crack tension specimen as shown in Fig. 9, that has length $2L = 3$ units, width $W = 1$ unit, and crack length $a = 0.5$ units. Due to symmetry, only a quarter of the plate is analyzed. Coupled FFEM-EFGM discretization and other parameters are same as those used in Example 1. The analytical solution of $K_I$ for DECT specimen given by Leung and Su [3], for different $a/W$ ratios is as follows:

$$K_I = \sigma \sqrt{\pi a} \left[ \frac{1.12 - 0.61 (a/W) + 0.13 (a/W)^3}{\sqrt{1 - a/W}} \right].$$  (39)

Similarly, the analytical solution of $T$-stress for DECT specimen with $L/W = 1.5$ is given by Fett [35], for different $a/W$ ratios.

Fig. 9. Double edge crack tension specimen with geometry and loads.

Figures 10a and 10b shows respectively the convergence of SIF ratio ($K_I/ (\sigma \sqrt{\pi a})$ by the proposed method/1.1756) and $T$-stress ratio ($T/\sigma$ by proposed method/−0.522) estimates with the

![Graph a) SIF Ratio vs. Similarity Ratio](image1)

![Graph b) T-Stress Ratio vs. Similarity Ratio](image2)

Fig. 10. Effect of similarity ratio (Example 2); a) convergence of $K_I$, b) convergence of $T$-stress.
similarity ratio $\xi$ employed, obtained using L9 elements for fractal mesh configurations of rectangular and circular shapes. It can be observed from Figs. 10a and 10b that accuracy increases with similarity ratio and that the circular fractal mesh configurations produce slightly better results when compared with those obtained using the rectangular mesh configurations.

Figures 11a and 11b show respectively the convergence of SIF ratio and $T$-stress ratio estimates with the number of fractal transformation terms used, obtained using L9 elements for fractal mesh configurations of rectangular and circular shapes. It can be observed from Figures 11(a) and 11(b) that the circular fractal mesh configurations produce slightly better results when compared with those obtained using the rectangular mesh configurations.

For crack length-to-width ratio $a/W = 0.5$, the angular variations of the stress components $\sigma_{rr}$, $\sigma_{\theta\theta}$, and shear stress, $\tau_{r\theta}$ at radial distance to crack length $r/a = 0.01$, are shown in Fig. 12. Figure 12 also include the plots of exact stresses from the LEFM singularity field near the crack tip [36], obtained by using the benchmark solution of $K/I/\left(\sigma \sqrt{\pi a}\right) = 1.1756$ units [3]. The predicted stresses from the proposed method match very well the exact stresses.

Figures 13a and 13b show respectively the estimates of $K/I/\left(\sigma \sqrt{\pi a}\right)$ and $T/\sigma$ as a function of $a/W$ ratio, obtained using L9 elements for fractal mesh configurations of rectangular and circular
shapes. Figures 13a and 13b demonstrate that the estimates of $K_I/(\sigma \sqrt{\pi a})$ and $T/\sigma$ as functions of $a/W$ ratio obtained using the proposed method, are in good agreement with the benchmark solutions of $K_I/(\sigma \sqrt{\pi a})$ [3] and $T/\sigma$ [35].

\begin{align*}
K_I &= \sigma \sqrt{\pi a} \left[ 1.0 - 0.5 (a/W) + 0.326 (a/W)^2 \right] \sqrt{(1 - a/W)}.
\end{align*}

Fig. 13. Effect of $a/W$ ratio (Example 2); a) $K_I$, b) $T$-stress.

6.3. Example 3: Center Crack Tension (CCT) Specimen

Consider a center crack tension specimen as shown in Fig. 14, that has length $2L = 3$ units, width $W = 1$ unit, and crack length $a = 0.5$ units. Due to symmetry, only a quarter of the plate is analyzed. Coupled FFEM-EFGM discretization and other parameters are the same as those used in Example 2. The analytical solution of $K_I$ for CCT specimen given by Benthem and Koiter [37], for different $a/W$ ratios, is as follows:

\begin{align*}
K_I &= \sigma \sqrt{\pi a} \left[ 1.0 - 0.5 (a/W) + 0.326 (a/W)^2 \right] \sqrt{(1 - a/W)}.
\end{align*}

Fig. 14. Centre crack tension specimen with geometry and loads.
Similarly, the analytical solution of $T$-stress for CCT specimen with $L/W = 1.5$ can be obtained from Fett [35].

Figures 15a and 15b show respectively the convergence of SIF ratio ($K_I/(\sigma\sqrt{\pi a})$ by the proposed method/1.1759) and $T$-stress ratio ($T(1 - a/W)/\sigma$ by the proposed method/−0.6236) estimates with the similarity ratio $\xi$ employed, obtained using L9 elements for fractal mesh configurations of rectangular and circular shapes. It can be observed from Figs. 15a and 15b that accuracy increases with the similarity ratio and that the circular fractal mesh configurations produce slightly better results when compared with those obtained using the rectangular mesh configurations.

configurations of rectangular and circular shapes. It can be observed from Figs. 16a and 16b that the circular fractal mesh configurations produce slightly better results when compared with those obtained using the rectangular mesh configurations.

For crack length-to-width ratio \( a/W = 0.5 \), the angular variations of the stress components \( \sigma_{rr}, \sigma_{\theta\theta}, \) and shear stress, \( \tau_{r\theta} \), at radial distance to crack length \( r/a = 0.01 \), are shown in Fig. 17. Figure 17 also includes the plots of exact stresses from the LEFM singularity field near the crack tip [36], obtained by using the benchmark solution of \( K_I/(\sigma\sqrt{\pi a}) = 1.1759 \) units [37]. The predicted stresses from the proposed method match very well the exact stresses.

Figures 18a and 18b show respectively the estimates of \( K_I/(\sigma\sqrt{\pi a}) \) and \( T(1 - a/W)/\sigma \) as functions of \( a/W \) ratio, obtained using L9 elements for fractal mesh configurations of rectangular and circular shapes. Figures 18a and 18b demonstrate that the estimates of \( K_I/(\sigma\sqrt{\pi a}) \) and \( T(1 - a/W)/\sigma \) as functions of \( a/W \) ratio obtained using the proposed method are in good agreement with the benchmark solutions of \( K_I/(\sigma\sqrt{\pi a}) \) [37] and \( T(1 - a/W)/\sigma \) [35].

7. Summary and Conclusions

This paper presents a coupling technique for integrating FFEM with EFGM for analyzing homogeneous, isotropic, and two-dimensional linear-elastic cracked structures subjected to Mode I loading condition. FFEM is adopted for discretization of domain close to the crack tip and EFGM is adopted in the rest of the domain. In the transition region interface elements are employed. The interface element shape functions which comprise both the element-free Galerkin and the finite element shape functions, satisfy the consistency condition, thus ensuring convergence of the proposed coupled FFEM-EFGM. The proposed method combines the best features of FFEM and EFGM, in the sense that no structured mesh or special enriched basis functions are necessary and no post-processing (employing any path-independent integrals) is needed to determine fracture parameters such as SIFs and $T$-stress. Three numerical examples are presented to illustrate the proposed method by calculating SIFs and $T$-stress. The convergence is checked against Q8 and L9 fractal mesh configurations. The convergence study includes: (i) the effect of the scaling parameter $z_{\text{max}}$ in the EFGM region on the solution; (ii) the effect of the integration order adopted in the FFEM region on the accuracy; (iii) the effect of the fractal mesh size on the accuracy; and (iv) the effect of different weight functions adopted in the EFGM region on the solution.

The present study indicates that using the proposed coupled FFEM-EFGM, convergent and accurate solutions can be obtained by adopting an exponential weight function along with the scaling parameter equal to 2.51, $2 \times 2$ Gaussian integration in the FFEM region, the number of fractal transformation terms equal to 20, and the similarity ratio equal to 0.8. The results are insensitive to the fractal mesh sizes in combination with the similarity ratio, the number of fractal transformation terms, and the similarity ratio considered in the present study. The nodal refinement in EFGM region alone has very little influence on the accuracy of solutions obtained using L9 elements, when compared with those obtained using Q8 elements. The convergence of the solutions with respect to the nodal refinement in the EFGM region alone, obtained using L9 elements, shows more stability than those obtained using Q8 elements. It is observed that L9 elements produce better results when compared with those obtained using Q8 elements. The predicted LEFM stress singularity field near the crack tip stresses from the proposed coupled FFEM-EFGM using L9 elements, match very well the exact stresses. The estimates of SIFs and $T$-stress obtained as a function of $a/W$ ratio using the proposed method are in good agreement with the benchmark solutions. Numerical examples based on Mode-I deformations show that the circular fractal mesh configurations produce slightly better results when compared with those obtained using the rectangular mesh configurations.
